Novel Method of Neuroprotection by Pharmacological Inhibition of AMP-activated Protein Kinase

10/593710

Background of the Invention

Stroke, defined as an abnormality in brain function resulting from disruption of
cerebral circulation, is one of the leading causes of death in the U.S. Even when a stroke
does not result in death, the costs it imposes on the victim may include serious physical
and emotional damage, which may result in loss of productivity. These costs stem from
the tremendous damage done to the victim's brain by the stroke. With a reduction in
oxygen and glucose, cells display a rapid disruption of protein synthesis, depletion of
intracellular energy stores, destabilization of the cell membrane, and activation of the
NMDA receptor, leading to excitotoxic and oxidative cell damage in the brain. In an
attempt to survive and repair the oxidative damage and return the cell to homeostasis,
numerous compensatory energy-consuming processes are activated. However, over-
activation of these pathways can deleterious, further depleting cellular energy, and
resulting in further brain damage. Such brain damage is, generally, irreversible.
Accordingly, a method of protecting brain tissue from damage during a stroke
(neuroprotection) would be tremendously important.

AMP-activated protein kinase (AMPK), a member of a metabolite-sensing protein
kinase family, is a known sensor of peripheral energy balance (Carling D., "The AMP-
activated protein kinase cascade- a unifying system for energy control." *Trends Biochem
Sci* 6:314 (2): 580-585, 2004.) AMPK is a heterotrimeric protein composed of a catalytic
α subunit (α1 or α2), and 2 regulatory subunits (β and γ). AMPK is phosphorylated and
activated when cellular energy levels are low. AMPK in turn regulates cellular
metabolism and chronically regulates gene expression to restore ATP levels. Increases in
the AMP/ATP ratio, changes in cellular pH and redox status, and increases in the
creatine/phosphocreatine ratio are known to activate AMPK (Hardie DG, Salt IP, Hawley
SA, Davies SP, "AMP-activated protein kinase: an ultrasensitive system for monitoring
cellular energy charge," *Biochem J* 338:717-22, 1999; Hawley SA, Davison M, Woods
A, et al., "Characterization of the AMP-activated protein kinase kinase from rat liver and
identification of threonine 172 as the major site at which it phosphorylates AMP-
activated protein kinase," *J Biol Chem* 271:27879-87, 1996.) AMPK increases fatty acid
oxidation and restricts fatty acid synthesis in an attempt to augment ATP levels in

energy-depleted cells. However, in neurons that have a restricted capacity for fatty acid oxidation, this effect could be deleterious (Almeida A, Moncada S, Bolanos JP, "Nitric oxide switches on glycolysis through the AMP protein kinase and 6-phosphofructo-2-kinase pathway," *Nature Cell Biology* 6: 45-51, 2004).

5   Inhibition of fatty acid synthase (FAS), the enzyme responsible for the de novo synthesis of palmitate, with C75, a synthetic FAS inhibitor disclosed in U.S. Patent No. 5,981,575 (incorporated herein by reference), increases ATP levels in a number of cell types, including neurons. AMPK is highly expressed in neurons in the hypothalamus, where it appears to play a role in the regulation of food intake. Hypothalamic

10   phosphorylated AMPK (pAMPK) is increased with starvation; C75 treatment inactivates and dephosphorylates AMPK, and induces profound anorexia.

The consequences of AMPK activation in neurons that do not have access to energy supplies is unknown. Until the present invention, it has been unclear whether AMPK activation during stress was protective or damaging. There have been no prior

15   studies examining the role of AMPK in stroke.

SUMMARY OF THE INVENTION

Applicants have invented a method of neuroprotection which comprises administering a compound to a patient who is experiencing or has experienced a stroke, the compound being an AMPK inhibitor.

20   Treatments with these agents significantly reduce the size of infarcts, and therefore minimize the loss of brain tissue and neurons. Thus, function can be preserved after stroke or ischemic injury in the brain. Similarly, neuronal loss can be minimized in degenerative diseases that cause neuronal compromise by perturbing energy utilization and availability in neurons.

FIG. 1 - Immunohistochemical localization of AMPK and pAMPK in ischemic mouse brain.

FIG. 2 - Immunohistochemical localization of PAMPK and NeuN in ischemic mouse cortex and hippocampus.

FIG. 3 - Time course of elevation of pAMPK after stroke.

FIG. 4 - Western blot analysis showing that AMPK phosphorylation is elevated after *in vitro* oxygen-glucose deprivation (OGD).

FIG. 5 - TTC staining and Western blot analysis shows the pAMPK is elevated in the ischemic and non-ischemic brain hemispheres.

FIG. 6 - Compound C treatment causes a significant decrease in regional and total stroke volume.

FIG. 7 - Administration of C75 leads to significant neuroprotection

FIG. 8 - Administration of AICAR, an AMPK activator, exacerbates stroke.

FIG. 9 - AMPK and pAMPK levels in wild type (WT) and neuronal nitric oxide synthase deficient mice (nNOS-/-).

FIG. 10 - AMPK and pAMPK levels in wild type (WT) and poly(ADP-ribose) polymerase (PARP-1) deficient mice

DETAILED DESCRIPTION OF THE INVENTION

By "neuroprotection," we mean protecting brain cells, preferably neurons, from permanent damage caused by a stroke during and after the stroke.

By "stroke," we mean an abnormality in brain function resulting from disruption of cerebral circulation.

By "AMPK inhibitor," we mean a compound which inhibits AMPK as determined by the method described by Witters, et al., *Journal of Biological Chemistry*, 267, pp. 2864-2867 (1992).

Preferably, the AMPK inhibitor is selected from a compound which is not a peptide or other biological (or biologically-derived) material, but is a small molecule.

The compositions of the present invention can be presented for administration to humans and other animals in unit dosage forms, such as tablets, capsules, pills, powders, granules, sterile parenteral solutions or suspensions, oral solutions or suspensions, oil in

water and water in oil emulsions containing suitable quantities of the compound, suppositories and in fluid suspensions or solutions. As used in this specification, the terms "pharmaceutical diluent" and "pharmaceutical carrier," have the same meaning. For oral administration, either solid or fluid unit dosage forms can be prepared. For

5   preparing solid compositions such as tablets, the compound can be mixed with conventional ingredients such as talc, magnesium stearate, dicalcium phosphate, magnesium aluminum silicate, calcium sulfate, starch, lactose, acacia, methylcellulose and functionally similar materials as pharmaceutical diluents or carriers. Capsules are prepared by mixing the compound with an inert pharmaceutical diluent and filling the

10   mixture into a hard gelatin capsule of appropriate size. Soft gelatin capsules are prepared by machine encapsulation of a slurry of the compound with an acceptable vegetable oil, light liquid petrolatum or other inert oil.

Fluid unit dosage forms or oral administration such as syrups, elixirs, and suspensions can be prepared. The forms can be dissolved in an aqueous vehicle together

15   with sugar, aromatic flavoring agents and preservatives to form a syrup. Suspensions can be prepared with an aqueous vehicle with the aid of a suspending agent such as acacia, tragacanth, methylcellulose and the like.

For parenteral administration fluid unit dosage forms can be prepared utilizing the compound and a sterile vehicle. In preparing solutions the compound can be dissolved in

20   water for injection and filter sterilized before filling into a suitable vial or ampoule and sealing. Adjuvants such as a local anesthetic, preservative and buffering agents can be dissolved in the vehicle. The composition can be frozen after filling into a vial and the water removed under vacuum. The lyophilized powder can then be scaled in the vial and reconstituted prior to use.

25   The subject is preferably a mammal, more preferably a human.

Dose and duration of therapy will depend on a variety of factors, including (1) the subject's age, body weight, and organ function (e.g., liver and kidney function); (2) the nature and extent of the disease process to be treated, as well as any existing significant co-morbidity and concomitant medications being taken, and (3) drug-related parameters

30   such as the route of administration, the frequency and duration of dosing necessary to effect a cure, and the therapeutic index of the drug. In general, does will be chosen to

achieve serum levels of 1 ng/ml to 100ng/ml with the goal of attaining effective concentrations at the target site of approximately 1 μg/ml to 10 μg/ml.

Ideally, the compound will be administered as soon as possible following the onset of the stroke.

5   Prior to this invention, the role of neuronal metabolism in the response to brain injury was unknown. Without wishing to be bound by theory, with this invention it is now known that pAMPK is elevated after ischemic stroke in a focal reperfusion model in mice. AMPK is elevated within 90 min of ischemic insult, and increases four-fold during early reperfusion. With this invention it is also now known that, administration of

10   AMPK inhibitors not only resulted in decreased activation of AMPK (as shown by decreased phosphorylation of AMPK), but also provided significant neuroprotection. It has also been found that administration of AMPK activators can exacerbate stroke damage.

While not wishing to be bound by theory, it is thought that AMPK, in addition to

15   playing a major role in physiological energy regulation, has far-reaching effects on cellular survival after ischemic stress. During ischemic stress energy demand is high, yet energy supply is low due to the lack of substrate (oxygen and glucose). By interfering with cellular energy perception and AMPK activation, the ischemic threshold of the cells may be augmented, allowing cells to survive in an energy deficient but quiescent state

20   until energy production can be restored. Modulation of metabolic pathways with synthetic FAS inhibitors/CPT-1 stimulators, such as C75, can alter neuronal metabolism, and create a positive energy balance. C75 inhibits AMPK in both cortical cultures and the hypothalamus in vivo, indicating that AMPK is responsive to neuronal energy balance. C75 administration leads to sustained increases in neuronal ATP levels in

25   cultured neurons. Under ischemic conditions continued ATP depletion may exceed energy restorative pathways, leading to an inability of the cell to die by the energy-consuming process of apoptosis, shunting cells into necrotic cell death. Thus, sensing ATP levels may be important in neuronal responses to ischemia and AMPK inhibitors may ATP and the neurons.

30   AMPK activation occurs after cerebral ischemia; in this setting, its activation is detrimental to neuronal survival. AMPK localized to neurons, and retained this pattern of

distribution (as opposed to glial localization) in the post-ischemic brain. AMPK was activated rapidly, within 90 minutes of vessel occlusion *in vivo*, and within 2 hours after oxygen glucose deprivation (OGD) *in vitro*. Increased levels of AMPK were seen throughout the brain, in both penumbral areas as well as in areas far removed from the

5 ischemic insult. Initially, this increase was thought to represent an adaptive response to neuronal stress, as a mechanism whereby the brain could increase ATP production in times of increased energy demand. Surprisingly, however, our pharmacological studies clearly demonstrate that inhibition of AMPK activation under conditions of neuronal ischemia *reduced* stroke damage. Administration of the AMPK inhibitor compound C, or

10 the FAS inhibitor C75, provided significant neuroprotection in our model. In contrast, administration of the AMPK activator AICAR exacerbated stroke damage. Lastly, nNOS deficient mice had both smaller infarcts and lower pAMPK levels after stroke, whereas mice deficient in PARP-1 had similar AMPK levels to WT despite smaller infarcts. This suggests that the nNOS and ONOO pathways are important activators of

15 AMPK *in vivo* under conditions of neuronal stress. Activation of neuronal AMPK is detrimental in an *in vivo* model of ischemia and reperfusion injury and that prevention of stroke-induced phosphorylation of AMPK is neuroprotective.

One well-characterized cytotoxin formed in ischemic cells is peroxynitrite (ONOO), a potent oxidant by-product formed when superoxide and NO are produced at

20 near equimolar amounts. There is a constant leak of superoxide from the mitochondrial respiratory chain, which is deactivated by endogenous antioxidants, such as superoxide dismutase (SOD). Under conditions of increased NO production, NO can out-compete SOD for superoxide resulting in ONOO formation. ONOO irreversibly inhibits enzymes, damages DNA, and activates the energy consuming, NAD-depleting DNA repair enzyme

25 poly(ADP-ribose) polymerase (PARP-1). Exposure of bovine endothelial cells to chemically synthesized ONOO activated AMPK without a change in AMP concentration, an effect replicated with hypoxia/re-oxygenation. These effects were ameliorated by adenoviral overexpression of SOD or administration of NOS inhibitors suggesting that ONOO mediated AMPK activation is mediated by NO. Recently, it was found that the

30 anti-diabetic drug Metformin can also activate AMPK independently of AMP levels by a similar mechanism. This suggests that the NO/ONOO pathway may be an important stimulus for AMPK activation. Our studies in nNOS-/- mice support this hypothesis, as

reductions in NO and ONOO formation seen in these animals led to a dramatic reduction in stroke-induced AMPK activation. However, male nNOS mice have significantly *smaller* strokes than their WT counterparts. It is possible that *any* manipulation that reduces ischemic damage would result in a decrease in pAMPK activation due to the

5   "milder" ischemic stress placed on the brain. Elevations in AMPK could simply represent a marker of increased ischemic damage. We addressed these questions by examining pAMPK levels in male mice with targeted deletion of PARP-1. Surprisingly, PARP-1 null mice had *an equivalent rise* in stroke-induced *pAMPK* compared to their WT despite significantly smaller (>50%) infarcts. This suggests that pAMPK elevation

10   is *not* simply a marker of increased ischemic damage but may be mechanistically related to ONOO and nNOS.

The consequences of AMPK activation to cell survival after ischemic insults *in vivo* were previously unknown. The majority of work has been done *in vitro*, often with transformed cell lines. AMPK activation with AICAR enhanced survival under

15   conditions of reduced energy availability (glucose deprivation and glutamate excitotoxicity) in cultured hippocampal neurons. However, numerous investigators have now documented a pro-apoptotic effect of AICAR on numerous cell lines, including hepatocytes, neuroblastoma cells, and mouse MMIN cells through stimulation of c-jun-N-terminal kinase (JNK), c-myc and capsase 3. In contrast, AICAR is protective in

20   ischemic cardiomyocytes and prevents ceramide-induced astrocytic apoptosis suggesting that the effects of AICAR are dependent on both the cell type and model system used. AICAR is taken up into the cell and accumulates in the cytoplasm as the monophosphorylated nucleotide, ZMP, which mimics the effects of AMP and activates AMPK without altering cellular ATP levels. However, AICAR is non-specific, and has

25   numerous other effects in the cell, including induction of adenosine, a known vasodilator via competition for nucleoside transport. AICAR reduced delayed cell death in the hippocampus after global ischemia in gerbils, but in this case AICAR was utilized an adenosine activator. In addition, the model of ischemic insult is quite different than our ischemia-reperfusion injury.

30   Our data demonstrate that activation of AMPK occurs in stroke, and that this response, when augmented by AICAR, exacerbates tissue damage. A limitation to the use of AICAR in *in vivo* studies was demonstrated by our physiological data, which

revealed a transient, yet significant drop in MAP in AICAR-treated mice. The reduction

in MAP may have increased infarction independently of effects on AMPK by a decrease

in perfusion of peri-infarct areas. Given the brevity of the drop, the maintenance of CBF

(via LDF (laser doppler flow)), and the dramatic neuroprotection seen with

5   pharmacological inhibition of AMPK, this is unlikely to be the primary explanation. In

addition, recent data suggests that AMPK activation is also detrimental to the ischemic

heart as cardiac injury induced by H_2O_2 was partially ameliorated by treatment with

Compound C similar to our findings in the CNS.

Whereas activation of AMPK may be beneficial in some peripheral tissues in

10   response to hypoxia, the situation in the CNS may be different. For example, in hypoxic

endothelial cells, eNOS is activated by direct phosphorylation by AMPK to presumably

alter vascular tone to enhance blood flow However, in stroke, this presumably beneficial

effect of AMPK may be of limited use, as cerebral blood flow (CBF) is severely reduced

during the acute occlusion (by the filament), making eNOS-induced vasodilation a futile,

15   energy consumptive process. In addition, under hypoxic conditions enhanced NO

production (via eNOS) can lead to increased levels of ONOO propagating free radical

injury.

Examination of both *in vivo* and *in vitro* systems is crucial in determining the

physiological outcome of AMPK activation. The severe ATP-depleting effects of

20   excessive NO exposure in neurons *in vitro* is mediated by *both* an inhibitory effect on

mitochondrial respiration as well as inhibition of glycolysis, which leads to reductions in

both oxidative and glycolytic energy production. However, in *astrocytes,* NO-induced

inhibition of respiration leads to an *increase* in astrocytic glycolysis with a reduction in

apoptosis. This rapid NO-dependent activation of astrocytic glycolysis is mediated by

25   AMPK activation with subsequent activation of phosphofructo-2-kinase (PFK-2).

Astrocytes therefore respond to stress and hypoxia with a compensatory increase in

glycolysis, providing energy and preventing cell death. Transfection of astrocytes with

AMPK siRNA renders astrocytes unable to increase glycolysis in response to NO, and

increased levels of apoptosis. Neurons, unlike astrocytes, lack the enzymatic machinery

30   to enhance glycolysis, as they have very low levels of PFK2 and restricted capacity for

fatty acid oxidation. Therefore, activation of AMPK under pathological conditions such

as stroke may not enhance *neuronal* survival.

Although focal stroke involves a discrete area of brain, compensatory mechanisms including changes in cerebral blood flow (CBF) and metabolic demand occur in areas far removed from the ischemic "core". For example, cerebral edema is seen in the contralateral "unaffected" hemisphere after large unilateral focal lesions, suggesting that

5   brain water content can vary in areas remote from the original injury. Communication with non-ischemic brain can occur through transcallosal or intrahemispheric "diaschisis", leading to impairments in CBF, electrophysiological activity, and metabolism. It is likely that the signal for AMPK activation is transmitted globally throughout the brain as is suggested by the robust contralateral rise in pAMPK levels.

10   Activation of AMPK increases stress in already compromised neurons. Interfering with cellular energy perception may augment the ischemic threshold, allowing cells to survive in energy deficient but quiescent state until energy production can be restored. Reducing AMPK activation could encourage "neuronal hibernation" early in the ischemic cascade, preventing complete neuronal energy failure, prolonging neuronal

15   viability until blood and nutrient supply can be restored. Improving energy dynamics in ischemic neurons allows for the possibility of prolonging the "therapeutic window" in clinical stroke. The suggestion that neuronal metabolic pathways may represent an important and novel target for neuroprotection is demonstrated by our findings.

The invention is further described by the following non-limitative examples:

20   *Examples*

Experimental Animals

The following experiments were conducted in accordance with NIH guidelines for the care and use of animals in research and under protocols approved by the Animal Care and Use Committee of the Johns Hopkins University.

25   *Ischemic Model*

Cerebral ischemia was induced by 120 minutes of reversible right middle cerebral artery occlusion (MCAO) under halothane anesthesia followed by reperfusion for various times for male C57B6 mice (Charles River) or male rats, as described by McCullough, et al., *Stroke*, 32, 796-802 (2001) and McCullough, et al., *J. Neuroscience*, 24, pp. 257-268

30   (2004), respectively. Intra-ischemic and 22 hour post-reperfusion neurological deficits

-9-

(NDS) were scored as follows: 0, no deficit; 1, forelimb weakness and torso turning to the ipsilateral side when held by tail; 2, circling to affected side; 3, unable to bear weight on affected side; and 4, no spontaneous locomotor activity or barrel rolling. Any animal without deficit was excluded from the study. At end-ischemia, the animal was briefly re-

5   anaesthetized and reperfusion was initiated by filament withdrawal. Sham animals were subjected to the equivalent surgical preparation, but the suture was not advanced into the internal carotid. For the pharmacological neuroprotection studies, mice survived 22 hours after reperfusion, at which time behavioral scoring was done. The brain was then harvested for pathological examination with TTC histology (see Histopathology section).

10   In separate animal cohorts, physiological measurements, femoral arterial blood pressure and cortical perfusion (laser Doppler flowmetry) were evaluated throughout MCAO and early reperfusion as described in the 2001 McCullough paper referenced above. Additional animals were exposed to ischemia or sham surgery after pharmacological or vehicle treatment and were sacrificed at 4 or 24 hours for Western blot analysis. Male

15   nNOS and PARP-1 deficient mice (see, Huang, et al., Science, **265**, 1883-1885 (1994); Eliasson, et al., *Nat. Med*, **3**, 1089-1095 (1997)) were subjected to 2-hour right MCAO or sham surgery and compared to additional WT cohorts (C57-BL6for nNOS-/- and SVEV for PARP-/-).

Terminal Histopathology

20   Infarction volume was analyzed by 2,3,5-triphenyltetrazolium staining in five 2-mm slices. Infarction volume was determined by video microscopy and image analysis (Inquiry 3, Loats Associates), as previously described by McCullough, et al., *J. Neuroscience* **23**, pp. 8701-8705 (2003).

Western blot analysis

25   Mouse and rat stroke and sham brain samples were obtained by rapid removal of the brain from the skull, resection of the cerebellum, followed by immediate dissection into the right (R) and left (L) hemispheres. Samples were flash frozen in liquid nitrogen. Samples from rats were further sub-dissected into core and penumbral regions for both hemispheres. Samples were stored at -80°C until use. Each sample was homogenized in

30   200 μl of lysis buffer (50 mM Tris-HCl, pH 7.5, 250 mM sucrose, 5 mM sodium pyrophosphate, 50 mM NaF, 1mM EDTA, 1mM EGTA, 1mM DTT, 0.5 mM PMSF,

0.1 mM benzamidine, 50 µg/ml leupeptin, 50 µg/ml soybean trypsin inhibitor). SDS detergent was added to a final concentration of 0.2%, and lysates were boiled for 5 min. After the supernatant was harvested, protein concentration was determined using a BCA kit (Bio Rad). 40 µg of protein was loaded per lane on a 4-15% gradient SDS-

5   polyacrylamide gel, and transferred to a polyvinylidene difluoride membrane. Blots were successively probed, stripped and reprobed for antigen detection.

Phosphorylation of AMPKα was determined using an anti-phospho-AMPKα (α1 and α2 Thr) antibody (1:1000, Cell Signaling). ACC (1:500), p-ACC (1:1000), pAkt (1:500), and Akt (1:500) antibodies were obtained from Upstate, Lake Placid, NY. Anti-

10   AMPKα antibody (anti-α1 and α2,1:1000; Cell Signaling), hsp-70 (1:1000; Santa Cruz), and β-actin (1:5000; Sigma) were used as loading controls. All blots were incubated overnight in primary antibody at 4°C in TBS buffer containing 5% BSA and 0.1% Triton-X-100. The secondary antibody (goat anti-rabbit IgG, Chemicon) was diluted to 1:5,000, and ECL (pico) detection kit was used for signal detection.

15   _Immunohistochemistry_

Floating brain sections were prepared as described by Kim, et al., _J. Biol. Chem.,_ **279,** 19970-19976 (2004) with modifications. Free-floating sections were blocked in PBS containing 5% goat serum, 1 mg/ml BSA, 0.05% Triton-X100, and 1 mM NaF for 1 hr at room temperature followed by incubation with anti-phospho-AMPKα antibody

20   (1:100), GFAP (1:1000, DAKO; for astrocytes), NeuN (Chemicon 1:100; a marker for mature neurons) or VWF (Santa Cruz; 1:400 for endothelial cells) in PBS containing 1% goat serum, 1 mg/ml BSA, 0.05% Triton-X-100, 1 mM NaF overnight at 4°C. The secondary antibody (1:200; Vector Laboratories; Burlingame, CA) was incubated in PBS containing 1% goat serum for 1 hr 30 min (Texas Red, FITC). The signal was visualized

25   with immunofluorescence confocal microscopy using Zeiss image acquisition software (Zeiss LSM 510).

Hippocampal slice culture and OGD

Hippocampal organotypic slice cultures were prepared as described by McCullough, et al., _Stroke_, **32,** 796-802 (2001) . Coronal hemispheric slices of 350

30   microns were derived from postnatal day 7 rat pups using a tissue chopper (McILwain

tissue chopper; Vibratome Company, St. Louis, MO). Hippocampal slices were
transferred onto 30 mm Millicell permeable membrane inserts (0.4 μm; Millipore,
Bedford, MA), in six well plates, with each well containing 1 ml of medium (50% MEM,
25% HBSS, 25% heat-inactivated horse serum, 6.5 mg/ml D-glucose, 5 U/ml penicillin

5   G, and 5 μg/ml streptomycin sulfate). Cultures were maintained in a humidified
incubator under 5% CO_2 at 37°C for 13 days. A complete medium change was
performed twice a week. Induction of anoxia was performed at 13 d *in vitro*. Slice
cultures were rinsed twice with warm BSS (in mM: 125 NaCl, 5 KCl, 1.2 NaH_2PO_4, 26
$NaHCO_3$, 1.8 $CaCl_2$, 0.9 $MgCl_2$, 10 HEPES, and 10 glucose), and returned to the

10   incubator to equilibrate for 30 min. Slice cultures were rinsed twice with warm
deoxygenated glucose-free BSS, transferred to an air-tight chamber, flushed with anoxic
gas (5% CO_2, 85% N_2, and 10% H_2), and maintained at 37°C for 60 min. Controls were
rinsed with BSS and transferred to a normal aerated incubator for 1 hr. The period of
anoxia was terminated by returning the cultures to fresh medium (50% MEM, 25%

15   HBSS, 25% heat-inactivated horse serum, 6.5 mg/ml D-glucose, 5 U/ml penicillin G, and
5 μg/ml streptomycin sulfate) and samples were prepared for western analysis at 2, 4, 6
and 24 hours (as above). Control and OGD-treated slices were included in each
experiment with triplicate wells or 15 slices per condition for each experimental group.

Statistical Analysis

20   All data are expressed as mean ± SEM. Physiological variables and histology
were analyzed by 1-way ANOVA with a post-hoc Newman-Keuls to correct for multiple
comparisons. Post-ischemic neurological scores were analyzed by the Mann-Whitney U
test. Values were considered statistically significant at *, $p < 0.05$; **, $p < 0.01$; ***,
$p < 0.001$

25   ### *Results*

AMPK is expressed in neurons post-ischemia

Brain tissue sections obtained from mice subjected to 2 hours of MCAO followed
by 2 hours of reperfusion showed prominent neuronal staining for both AMPK and
pAMPK (Fig. 1, n=5/gp). They were also stained with NeuN (for mature neurons),

30   GFAP (for astrocytes). Confocal microscopy demonstrates co-localization of NeuN and
AMPK/pAMPK, with absent co-lacalization in astrocytes.   BEST AVAILABLE COPY

Confocal microscopy demonstrated that AMPK (Fig. 1 A-C) and pAMPK (Fig. D-F) localized to cortical neurons in the middle cerebral artery (MCA) distribution, as shown by double labeling immunofluorescence using the mature neuronal marker NeuN. Higher magnification of cortical neurons immunostained for NeuN and pAMPK (Fig. 1

5   G-I) shows nuclear and cytoplasmic immunostaining for the α isoform. While AMPK may be only minimally expressed in non stimulated astrocytes in intact brain, previous studies have found AMPK immunoreactivity in cultured astrocytes. To clarify the localization of AMPK and pAMPK *in vivo*, we examined both normal non-ischemic tissue as well as brains harvested both 4 and 24 hours after infarction (at 2 or 22 hours of

10   reperfusion) to determine whether AMPK is expressed in astrocytes after stroke. There was only minimal co-localization of GFAP with AMPK or pAMPK 4 hours after MCAO (Fig. 1 J-L and Fig. 1 M-O, respectively). Similar to 4-hour tissue, no co-localization of AMPK or pAMPK with GFAP was seen in cortex 24 hours after stroke (Fig. 1 P-R). In addition, no co-labeling of either AMPK or pAMPK with the endothelial marker von

15   Willebrand factor (VWF) was seen in intact or ischemic brain (data not shown). To determine if this pattern of pAMPK immunolocalization was retained regionally, low power images of pAMPK and NeuN double labeling were obtained at 24 hours after infarction (22 hours of reperfusion) (Fig. 2). Similar levels of staining were seen in both the cortex (Fig. 2A-C) and the hippocampus (Fig. 2D-F), with prominent pAMPK co-

20   labeling with NeuN in both regions. No signal was seen in control sections without addition of primary antibody (data not shown). These results show that AMPK is expressed primarily in neurons in both the ischemic and non-ischemic brain, where it may function in a cell-autonomous manner to influence neuronal energy balance.

AMPK is increased after MCAO

25   Male wild-type (WT) C57B16 mice were subjected to 2-hour right MCAO or sham surgery with varying reperfusion times. Physiological parameters, such as temperature, were held constant. There were no significant differences in physiological measurements between each treatment group compared to respective vehicle in C75 and Compound C (Cpd C) treated animals. MAP and LDF are shown averaged over the 2

30   hours of ischemia. AICAR treated animals had a significant reduction in MAP at 15 minutes ($p < 0.05$), with no overall difference over 2 hours of monitoring. Reductions in

- 13 -

intraischemic LDF were equivalent in Vehicle and AICAR animals, however there was a significant reduction ($p<0.05$) in LDF at 30 minutes of reperfusion (n=4/group):

As can be seen in Fig. 3, pAMPK (as detected by a panα subunit antibody to Thr phosphorylation site (see, Hawley, et al., *J Biol Chem* 271, 27879-27887 (1996)) was elevated in ischemic brain (Stroke) as early as 90 minutes following ischemia compared to animals that had undergone sham surgery (Sham) (n=6 per time point for ischemic animals; 4 per time point sham operated controls). pAMPK levels were elevated in the right, ischemic hemisphere (R) and on the left, non-ischemic hemisphere (L), and remained elevated for 24 hours (22 hours of reperfusion) in both the ischemic right and the non-ischemic left hemispheres. In contrast, pAMPK levels in sham brains remained stable over the 24-hour period. Total AMPK levels showed minimal changes. Appropriate elevations of hsp-70 were seen in the ischemic hemisphere although these were most notable at later time points (ie., 6, 12 and 24 hours). β-actin served as a loading control. The global increase in pAMPK levels suggests that AMPK is activated secondary to metabolic derangements and compensatory responses not only in the ischemic area, but also in the contralateral nonischemic side.

AMPK is activated after OGD in vitro

In addition to the *in vivo* findings, we also determined whether AMPK was activated *in vitro* in hippocampal slice cultures after oxygen-glucose deprivation (OGD).

BEST AVAILABLE COPY

an *in vitro* model of stroke. We found a robust increase in pAMPK levels 2 hours after

OGD compared to normoxic normoglycemic control cultures (Fig. 4A). This increase in

pAMPK persisted at 6 hours, but normalized by 24 hours, as was seen in our *in vivo*

studies. A downstream target of AMPK activation is acetyl-CoA carboxylase (ACC),

5   which is the pace-setting enzyme in the *de novo* synthesis of fatty acids; when activated,

AMPK mediates the phosphorylation of ACC, thus inactivating ACC, and limiting the

anabolic process of fatty acid synthesis in times of energy deficiency. Evaluation of slice

samples 4 hours following OGD demonstrated an increase in the level of phosphorylated

or inactivated acetyl-CoA carboxylase (pACC) (Fig. 4B), supporting the idea that the

10   observed increases in pAMPK are physiologically relevant. Total AMPK and ACC

levels changed minimally at all examined time-points in both OGD or control slices.

AMPK elevation is seen in the ischemic penumbra

Assuming that metabolic derangements in stroke may be more severe in the

necrotic core of an infarct, whereas pro-survival pathways may be activated in the

15   penumbra in an attempt to salvage marginally functioning brain, we dissected out core

(CC) and penumbral (PC) tissues from both the ischemic right hemisphere (IH, ischemic

hemisphere) or non-ischemic left hemisphere (NIH; non-ischemic hemisphere) for

Western blot analysis from rat brains (n=6/group) 6 hours after stroke (Fig. 5). Rats were

used for this experiment, as dissection of core and penumbra is more rapidly and reliably

20   done using the larger rat brain; this also allowed us to confirm our findings in a different

species. The areas of ischemia and of dissection were visualized using TTC staining at

24 hours (Fig. 5A). pAMPK levels were dramatically elevated in the cortical penumbral

non-ischemic hemisphere and in the contralateral non-ischemic hemisphere (PC NIH and

CC NIH, respectively), compared to pAMPK levels in either hemisphere in the sham

25   brain (PC and CC) (Fig. 5B). pAMPK levels in the ischemic core (CC in the ischemic

hemisphere) were lower than in the other areas of brain, but were elevated compared to

surgical shams (Sham CC and PC).

It is possible that the lower level of AMPK in the core represents failure of protein

synthesis and energy-dependent phosphorylation in the ischemic core of the infarct.

30   However, expected increases in heat-shock protein 70 (see, Kury, et al., *Eur J Neurosci*

19, 1708-1720 (2004)) were seen. Alternatively, AMPK activation could represent a

compensatory protective pathway in the penumbra. pAMPK could be up-regulated in neurons that are damaged, but remain viable, as a strategy to increase available energy supply. The rise in contralateral AMPK suggests that neurons far removed from the area of the insult may also be receiving a signal to increase energy availability. Therefore,

5   increases in pAMPK levels and thus activity could represent an adaptive, endogenous neuroprotective pathway. To address this issue, we proceeded to pharmacologically manipulate AMPK levels to determine the effect of changing pAMPK levels to stroke outcome.

Compound C reduces pAMPK levels and is neuroprotective

10   To examine the functional effects of AMPK activation in this ischemic model, we explored the effect of stroke outcome in mice treated with compound C, a pharmacological AMPK inhibitor described in _J. Clin Invest_ 108, pp. 1167-1174 (2001). The effect on stroke outcome in animals treated with Compound C (20mg/kg delivered intraperitoneally; n=14) or vehicle (n=8) at stroke onset (2-hr MCAO with 22 hr

15   reperfusion) was determined (Fig. 6). Compound C significantly reduced total infarct volume (as measured by % non-ischemic hemisphere, corrected for edema using TTC), as well as striatal (CP; 64 ± 5.7 vs. 21 ± 3.9; $p>0.001$) and cortical (CTX; 63 ± 3.4 vs. 19.4 ± 3.3; $p<0.001$) infarct volumes compared to vehicle treated animals (Fig. 6A). A reduction in severity of behavioral deficits at 24 hours reflected these differences (vehicle

20   3.3 ± 0.3 vs. compound C 1.9 ± 0.2, $p<0.01$). There was no difference in relative cerebral blood flow (CBF) as measured by laser Doppler, either during the intraischemic period (vehicle=9.8 ± 0.54 vs. compound C=10.6 ± 0.9; % of baseline; $p=$n.s.), or during the 30 minutes after reperfusion, suggesting that differences in blood flow could not account for the differences in ischemic damage. No differences in physiological measurements were

25   seen between treatment groups (Table 1) demonstrating the equivalent contribution of these factors to stroke outcome.

Additional groups of vehicle or compound C treated mice subjected to either 2 hours MCAO (n=6/group) or sham surgery (n=4/group) were sacrificed 4 hr (Fig. 6B) or 24 hr (Fig. 6C) after infarction for determination of AMPK and pAMPK levels. Lysates

30   from either the ischemic (right, R) or non-ischemic (left, L) hemispheres were analyzed by Western blot analysis in both stroke and sham surgery animals. The anticipated

increase in pAMPK 4 hr after infarction (2 hours of reperfusion) was seen in vehicle treated animals (Fig. 6B, lanes 1 and 2) relative to sham animals (lanes 3 and 4), but the levels of pAMPK were reduced in compound C treated animals (lanes 5 and 6); total AMPK levels were unchanged. The effect of compound C was transient; pAMPK levels

5   were similar to that seen in vehicle-treated mice by 24 hr (Fig. 6C, lanes 1 and 2 compared to lanes 5 and 6). These results suggest that the inhibition of AMPK with compound C is neuroprotective, and that this neuroprotective effect correlates with a reduction in pAMPK levels.

Reduction in pAMPK levels by the FAS inhibitor C75 is neuroprotective in stroke.

10   We administered the FAS inhibitor C75 (20 mg/kg i.p.) or vehicle (RPMI) immediately prior to the onset of ischemia (n=9/gp). We based this dose on previous in vivo data that demonstrated an effect on feeding behavior and an inhibition of C75 activity in hypothalamus. There was a significant reduction in total and regional infarction volume seen in the C75-treated group (p<. 001). Improvements in behavioral

15   scores were seen (vehicle 3.2±. 05 vs. C75 2.0±. 03, p<. 01). As with compound C, no differences in LDF or physiological variables were seen (n=4). Additional groups of vehicle or C75 treated mice subjected to either 2-hour MCAO and reperfusion (n=6/group) or sham surgery (n=4/group) were sacrificed 4 hr (Fig. 7B) or 24 hr (Fig. 7C) following stroke for analysis of AMPK and pAMPK levels. The anticipated increase

20   in pAMPK at 2 hr of reperfusion was seen in both and C75-treated vehicle-treated mice (Fig. 7B, lanes 1 and 2 vs. lanes 5 and 6, respectively), although the increase in pAMPK levels was blunted by C75 treatment. As with compound C, the reduction in the increase in pAMPK levels was more pronounced in the ischemic right hemisphere (R) compared to the non-ischemic left hemisphere (L). Compared to vehicle-treated mice, C75 reduced

25   pAMPK levels in both sham and stroke mice prominently 24 hr following stroke (Fig. 7C, lanes 1-4 vs. lanes 5-8, respectively), indicating a more lasting central effect of C75 (compared to compound C) in reducing pAMPK levels.

As shown in Fig.5A, there was a significant reduction in total and regional infarction volume seen in the C75-treated group (P<.001). There were no significant

30   differences in intra-ischemic or reperfusion blood flow blood flow as measured by laser Doppler nor were there any differences seen in MAP, pH or blood gas measurements in

the non-survival cohort (n=4, data not shown). Additional groups of vehicle or C75 treated mice subjected to either 2-hour MCAO (n=6/gp) or sham surgery (n=4/gp) were sacrificed at 4 hr (Fig 5B) or 24 hr (Fig. 5C) after stroke for analysis of AMPK and pAMPK levels. The anticipated increase in pAMPK at 2 hr of reperfusion was seen in vehicle and C75-treated mice. Reductions in pAMPK levels were seen in C75 treated animals at 24 hrs in both sham and stroke mice, documenting the more lasting central effect of C75 (compared to compound C) in reducing pAMPK.

AMPK activation with the AMPK activator 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR) exacerbates stroke.

The widely used AMPK activator, 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR), (see, Corton, et al., *Eur J Biochem*, **229**, 558-565 (1995)) was administered at stroke onset (500mg/kg i.p.; n=11/group). AICAR is taken up into cells and phosphorylated to form ZMP, which mimics the effects of AMP on AMPK activation. There was a significant exacerbation of total and cortical (CTX) stroke volumes in AICAR-treated animals (Fig. 8A). Physiological monitoring demonstrated a significant drop in mean arterial pressure (MAP) in AICAR treated animals that self-corrected by 15 minutes after injection (MAP vehicle 84 vs. AICAR 69 mmHg, $p < 0.05$). There were no differences in intraischemic CBF, but a reduction in CBF was seen in AICAR-treated mice compared to controls at 30 minutes after reperfusion (98 vs. 82.7 % of baseline, $p < 0.05$). This suggests that part of the detrimental effects of AICAR may be secondary to decreased perfusion pressure, in addition to its effects on AMPK. Western blot analysis showed elevations of pAMPK 4 hr following stroke (2 hours of reperfusion) in AICAR treated vs. vehicle treated animals (Fig. 8B lanes 5-8 vs. lanes 1-4, respectively), which returned to baseline by 24 hr (data not shown).

Loss of nNOS prevents stroke-induced elevations in pAMPK

As ONOO (peroxynitrite) is a significant contributor to stroke-induced neuronal damage, and AMPK is activated by ONOO as well as hypoxia *in vitro*, we evaluated the role of neuronal NOS (nNOS) in AMPK activation after stroke (Fig. 9). nNOS knockout animals have significantly smaller infarcts than their wild-type counterparts, primarily due to a reduction in ONOO production. We confirmed the neuroprotective effect of nNOS deletion in our MCAO model (total infarct: 55.8±4.9% in WT; 31.9±4% in nNOS-

/-; p<0.01). Male nNOS-/- and wild type (WT) mice were subjected to right MCAO, and brains were harvested at either 4 hr (Fig. 9A) or 24 hr (Fig. 9B) following infarction (22 hours of reperfusion). At 4 hr, WT mice showed an elevation in pAMPK compared to WT sham in both the ischemic (right, R) and non-ischemic (left, L) hemispheres.

5 However, in nNOS-/- mice, the stroke-induced rise in pAMPK levels was abrogated, and pAMPK levels were similar to sham. Similar results were found at 24 hr (Fig 9B). Levels of phosphorylated Akt were also decreased in nNOS-/- mice compared to WT at 24 hr after infarction (22 hours of reperfusion), suggesting a possible relationship between Akt, AMPK, and NOS (Fig 9C).

10 As the decreased activation of AMPK in nNOS-/- mice might simply be a reflection of the decreased ischemic damage seen in this strain, we also examined male mice deficient in the DNA repair enzyme Poly (ADP-ribose) polymerase-1 (PARP-1 knockout mice), which have similar reduction in stroke volumes to nNOS-/- male mice (Fig. 10). Surprisingly, PARP-1 deficient mice had similar levels of pAMPK activation

15 in the ischemic hemisphere compared to their respective WT (Fig 10, only ischemic hemisphere shown) despite smaller infarcts. This suggests that reductions in NO or ONOO production seen in nNOS deficient mice lead to the selective amelioration of AMPK activation.
